Coupling metrics to diagnose land-atmosphere interactions

Vegetated Coupling (Little Omega)

• Principle:

o A "decoupling parameter" based on the ratio of canopy conductance (g_c) versus aerodynamic conductance (g_a) scaled by moisture holding capacity of the atmosphere:

$$W = \left[\left(\frac{g}{m+g} \right) \frac{g_a}{g_c} + 1 \right]^{-1}$$

indicates strong/weak coupling <u>over vegetated surfaces</u> as $W \rightarrow 0, 1$. g is the psychrometric constant, m is the slope of saturation vapor pressure with temperature.

 More intuitive is a scale where 1 indicates strong and 0 indicates weak coupling, an actual "coupling parameter":

$$W = \left[\left(\frac{m+g}{g} \right) \frac{g_c}{g_a} + 1 \right]^{-1}$$

 An additional term can be defined for soil heat flux modulation of coupling (see Ek et al. 2016).

• Data needs:

 LSM and/or GCM output often has all needed terms for model diagnosis. From a theoretical viewpoint, it is easy to plot distributions as a function of varying conductances, or the terms that determine those conductances.

• Observational data sources:

 \circ g_c is very difficult to measure or estimate in the field, largely restricting this metric to LSM output or laboratory situations unless special instrumentation is deployed.

• Caveats:

 See Ek et al. (2016) for a full discussion including the derivation and relationship to evaporative fraction for transpiration.
